ABSTRACT

The specific and functional diversity of the rabbit digestive ecosystem is highly diverse. The digestive ecosystem has several physiological roles: hydrolysis and fermentation of nutrients, immune system regulation, angiogenesis, gut development and acting as a barrier against pathogens. Understanding the digestive ecosystem and how to control its functional and specific diversity is a priority, since this could provide new strategies to improve the resistance of the young rabbit to digestive disorders and improve feed efficiency. This review first recalls some facts about the digestive microbiota composition in the main fermentation compartment, and its variability in rabbits and other species with some new insights based on recent molecular approaches. The main functions of the digestive microbiota will then be explained. Finally some possible ways to control rabbit caecal microbiota will be described and a suitable timing for action will be defined.

Key words: Microbiota, implantation, digestive efficacy, immune system development, health, rabbit.

INTRODUCTION

Mammals can be regarded as super-organisms as they are permanently colonized by a vast and rich community of microorganisms. There is a host / microbiota relationship based on a model of symbiosis that defines "the digestive ecosystem" where each partner benefits from the association. Indeed, microorganisms colonize and grow rapidly under the favourable conditions of the gut, while the rabbit obtains the products of microbial fermentation from materials that could otherwise not be digested. In rabbits this association is called a combined competition-cooperation model (Mackie, 2002). However, the balance of this ecosystem is fragile and may be disturbed during digestive disorders. In recent years a considerable research effort using the techniques of molecular biology and microbiology have helped define its composition, understand its functioning and its many physiological roles: hydrolysis and fermentation of nutrients, immune system regulation, motility effects, angiogenesis and intestinal trophism, and acting as a barrier against infectious agents.

Control of the microbiota could therefore improve digestive efficiency or immune status and thus digestive health. Improved digestive efficiency through optimization of the composition of the microbiota has a direct impact on feed costs, and would also increase the use of "fibrous" raw materials useless for human consumption. Similarly, improving digestive efficiency would reduce emissions to the environment. Note that unlike ruminants, reducing the emission of greenhouse gases is not a major issue of the rabbit industry since the growing rabbit produces little methane (Franz et al., 2011). Finally, control of the microbiota could limit digestive problems around weaning, firstly through its barrier effect and partly through its role as immune stimulator. In this review, we will endeavour to take stock of knowledge about the composition and functioning of the ecosystem in the rabbit caecum. This paper highlights the physiological roles of the microbiota and the benefits for the host. Furthermore we will evaluate the possibility of engineering the microbiota to produce a better outcome for the host. The applied objectives are to reduce the frequency of occurrence of digestive disorders and / or to improve feed efficiency.
1. Specific diversity of the rabbit gut ecosystem

The digestive tract of animals, and particularly of mammals, is a habitat very conducive to the development of microorganisms. Indeed, the transit speed is quite slow, the acidic to neutral pH of the medium is associated with high humidity and a high and stable temperature. The intestinal microbial community, called microbiota, is abundant, since it consists of about 100 to 1000 billion microorganisms per gram of digesta. Its diversity and complexity is very high, with about a thousand different species. In rabbits, an abundant microbiota ($10^{10}$ to $10^{12}$ bacteria / g) is present throughout the caecum-colon and in hard and soft faeces, and has also been studied in the ileum where its abundance is lower ($10^6$ to $10^8$ bacteria / g). Bacteria predominate, (Gouet and Fonty, 1973; Forsythe and Parker, 1985; Combes et al., 2011), while the archaeal population is estimated at $10^7$ per g of content (express in copy 16S RNA gene Combes et al., 2011 ) (Figure 1). Regarding eukaryotes, the rabbit caecal digestive ecosystem appears to lack anaerobic fungi (Bennegadi et al., 2003) and yeast (Kimsé et al., 2012) although commensal yeasts have been found in the caecum ($10^6$ /g Forsythe and Parker, 1985). Protozoa are absent from the caecal ecosystem (Bennegadi et al., 2003) except in animals suffering from coccidiosis (Lelkes and Chang, 1987).

1.1. Microbiota taxonomic composition

The taxonomic diversity of the rabbit digestive ecosystem was first studied by culture techniques (Fonty and Gouet, 1989). These studies, based on the functional aspect of microorganisms and their ability to grow on defined substrates, have shown that the adult rabbit hosts $10^7$ and $10^6$ CFU (colony forming unit) of cellulolytic bacteria per gramm of caecal contents and faeces, respectively. Populations of pectinolytic and xylanolytic bacteria are between $10^9$ and $10^{10}$ CFU bacteria per gramm in the colon and caecum. Cultivable species most frequently identified were *Eubacterium cellulosolvens* for cellulolytic bacteria and *Bacteroides ruminicola* for pectinolytic and xylanolytic bacteria (Boulahrourf et al., 1991). Moreover, the cultivable fraction of the rabbit digestive microbiota in healthy adults was characterized by the absence or low density of *Lactobacillus*, *Streptococcus* and *Escherichia coli* (Ducluzeau, 1969; Gouet and Fonty, 1973; Fonty et al., 1979; Yu and Tsen, 1993; Padilha et al., 1996) and predominance of *Bacteroides* (Gouet and Fonty, 1973; 1979 ).
However, these culture techniques allow to study only of a little part of the existing population, since very little is known about the physiology of many organisms to be isolated and grown in vitro. Suau et al., (1999) demonstrated using microscopic counts on human faeces that 60 to 80% of the observable bacteria cannot be cultivated. In the last ten years, molecular microbiology techniques have led to substantial progress in the knowledge of the microbial diversity of digestive ecosystems. These techniques are often based on the use of genes encoding RNA of the small 16S subunit of prokaryotic ribosomes (16S rDNA) (Deng et al., 2008). This molecule is a good marker of the diversity of prokaryotes. Indeed, it is ubiquitous (present in all prokaryotes), and contains highly conserved areas and other highly variable that distinguish families and genera of them. Moreover, it is easily detectable because of its large number of copies. Finally the 16S rDNA is a neutral marker of evolution: this molecule has evolved over time in the absence of selective pressure, thus it allows us to classify the microorganisms but also to understand their evolution (Case et al., 2007). There are several methods using 16S rDNA to study microbial diversity: quantification by real-time PCR, cloning (Abecia et al., 2005; Monteils et al., 2008; Kušar and Avguštin, 2010) and molecular fingerprinting (DGGE, RFLP, CE-SSCP etc...) (Abecia et al., 2007a; Abecia et al., 2007b; Abecia et al., 2007c; Chamorro et al., 2007; Gomez-Conde et al., 2007; Gómez-Conde et al., 2009; Michelland et al., 2010a; Michelland et al., 2011). This provides a representative picture of the whole bacterial or archaeal community quickly and cheaply (Figure 2A and 2C). The RFLP technique also refers to a database and provides a probability of the presence of specific bacteria. The structure of these fingerprints combined with the diversity index calculation are used to study the dynamics of the microbiota, for example as a function of age or nutritional factors. More recently deep 16S rDNA pyrosequencing was developed, which could be considered as a 2nd generation 16S rDNA fingerprinting (Lamendella et al., 2012) has been developed. It provides a more complete picture of the composition of gut microbial inhabitants than previous techniques and provides considerable knowledge about the identity of the dominant member of the community (Lamendella et al., 2012). Currently, the development of high-throughput ‘omics’ methods, make it possible to investigate all levels of biological information of complex microbial communities. Indeed, metagenomics, metatranscriptomics, metaproteomics and metametabolomics are employed to explore at a given time within an ecosystem the DNA sequences, the collectively transcribed RNA, and the translated proteins and the metabolites resulting from cellular processes respectively (Siggins et al., 2012). In rabbits, deep 16S rDNA pyrosequencing was recently performed and has described for the first time the relative abundance of the main genera present in the caecal ecosystem (Figure 2B)(Massip et al., 2012). Moreover, an initial study of functional metagenomics in rabbits has allowed the characterization of caecal cellulase enzymes as yet unknown (Feng et al., 2007).

Three teams have performed a molecular inventory in the rabbit caecum using 16S rDNA. Two teams have explored the bacterial community (46 Abecia et al., 2005 588; and 228 clones Monteils et al., 2008) while one team has explored the archeal community(34 clones Kušar and Avguštin, 2010). Both bacterial community inventories revealed a lack of knowledge about the bacterial species living in the caecum. Indeed, most of the identified sequences correspond to new uncultivated bacterial species not found in the databases (90% Abecia et al., 2005; 80% Monteils et al., 2008). These studies also showed the uniqueness of the rabbit caecal microbiota, since half of the sequences described in each study are phylogenetically close to each other. Phylogenetic analysis (Table 1) listed the overwhelming majority of the sequences in the Firmicutes (over 90% of sequences), while the Bacteroidetes represented only 4%. In agreement with these results, the Firmicutes population density of adult rabbits, as assessed by real-time PCR, was 10.8 log_{10} copies of 16S rDNA / g of caecal...
contents, while the genera *Bacteroides* and *Prevotella* density was ten times lower (9.7 log_{10} copies of 16S rDNA / g) (Combes et al., 2011) (Figure 1). In the same way, deep 16S rDNA pyrosequencing of caecal content of the rabbit (at 63d old) showed a preponderance of the *Firmicutes* phylum (about 90%), followed by *Bacteroides* (4.6%), then *Actinobacteria* (0.9%) and *Proteobacteria* (0.7%). Within the *Firmicutes* phylum, the families of *Ruminococcaceae* and *Lachnospiraceae* were dominant (45% and 35% of whole sequences, respectively) (Massip et al., 2012).

Although the bacterial kingdom is the most abundant in the digestive ecosystems, particular interest has been focused in recent years on *archaea*. Indeed, *archaea* that reside in the digestive tract are all strictly anaerobic methanogenic. Integrated at the end of the food chain, they allow the elimination of H\(_2\) from fermentation to provide methane (Jones et al., 1987). Methane is a powerful greenhouse gas (23 times as warming as CO\(_2\)) and also represents a loss of 6 to 8% of the energy and carbon ingested by the animal (Boadi et al., 2004). In rabbits, the data on the archaeal community are limited. Methanogenesis was first observed in vitro (Piattoni et al., 1996; Marounek et al., 1999; Yang et al., 2010; Belenguer et al., 2011) and more recently in vivo using respiratory chambers (Belenguer et al., 2011; Franz et al., 2011). The simplicity of the CE-SSCP profiles obtained for the archaeal community (Figure 2C) indicates a much lower species diversity than the bacterial population (Figure 2A). Indeed, archaea diversity is low in the mammalian digestive ecosystems. The order that prevails is the order of *Methanobacteriales* with *Methanobrevibacter* as main genus (sometimes associated with some *Methanomicrobium, Methanobacterium* and *Methanosarcina* (Order: *Methanosarcinales*) (Jarvis et al., 2000; Wright et al., 2007). The molecular inventory of the archaeal population recently made for rabbits (Kušar and Avguštin, 2010) confirmed the predominance of the genus *Methanobrevibacter* and suggested the presence of a new species specific to rabbit. Archaea density was estimated at 7-8 log_{10} 16S rDNA copies / g of caecal contents (Figure 1). In vitro, the amounts of methane excreted depend on the diet of the rabbits (Belenguer et al., 2011) or the nature of the substrate placed in the presence of inoculum (Yang et al., 2010). Great variability of methane excretion was observed in vivo between individuals (excretion of methane was detected only in two individuals out of sixteen: Belenguer et al., 2011). This suggests the existence of a genetic effect but also the existence for some non-methano-excreting rabbits of another route for the elimination of H\(_2\), i.e. reductive acetogenesis. The amount of energy lost as methane is lower in rabbits than in dairy cows (1% vs. 6% of gross energy ingested Vermorel, 1995; Franz et al., 2011).

**Figure 2:** CE-SSCP profile (A), 454 pyrosequencing profile (B) of the bacterial community and CE-SSCP profile of the archaeal community (C) in rabbit caecum.

### 1.2. Microbiota structuring

#### 1.2.1 Spatial Structuring of microbiota

Although the caecum is the primary fermenter in rabbits, a microbial population is also present in the proximal (stomach, small intestine) and distal (colon) segments of the gastrointestinal tract (Gouet and Fonty, 1979). The stomach of rabbits contains 10\(^4\) - 10\(^8\) CFU bacteria / g in adulthood. The small intestine contains 10 - 100 fold more bacteria. The colon has a population similar to that of the caecum (Gouet and Fonty, 1979), which is still 100 - 1000 times more than in the ileum. Bacterial diversity is higher in the ileum than in the caecum according to fingerprinting (Badiola et al., 2004; Martignon et
This difference is surprising since a faster passage of food particles in the ileum, would not be favourable to bacterial proliferation and diversity. Moreover, the bacterial density of soft faeces, which correspond to the caecal contents slightly modified, is of the same order of magnitude as that of the caecum \(10^{11}\) bacteria \(g\). Conversely, the bacterial density of faeces, which are richer in large particles \(>0.3\ \text{mm}\), is 10 times lower than that in the caecum \((\text{Emaldi et al., 1978})\). Similarly, the structure of the archaeal and bacterial community of soft faeces is closer to that of the caecal content than that present in the faeces \((\text{Figure 3})\) \((\text{Rodriguez-Romero et al., 2009; Michelland et al., 2010a; Michelland et al., 2010b})\). The feature of the spatial structure of the community is mainly due to the differences or similarities in chemical composition between the different digestive compartments. Indeed, the physicochemical factors of the ecosystem play a major role in the selection of species of microorganisms, each of which has specific physiological characteristics. The physicochemical parameters that play a major role for a gut ecosystem are: the absence of light energy, constant and relatively high temperature \(35 \text{ to } 40^\circ\text{C}\), humidity \(75-95\%\), slightly acidic to neutral pH \(6 \text{ to } 6.5\), relatively low redox potential, \(<200\text{mv Kimsé et al., 2009}\). In conclusion, studies in different gastrointestinal segments of the rabbit suggest the use of soft faeces for monitoring the dynamics of the microbiota of the caecum, limiting thus surgery or sacrifice of the animal.

1.2.2. Temporal dynamics of the microbiota

In the absence of induced perturbations, the bacterial community of the adult rabbit caecum \((\text{diversity, structure, total bacteria densities, Firmicutes and the Bacteroides Prevotella})\) remained stable over time \((\text{Michelland et al., 2010a; Michelland et al., 2011})\). In agreement with observations made in man \((\text{Zoetendal et al., 1998; Vanhoutte et al., 2004})\), the absence of temporal variations in the rabbit caecal microbiota adult shows a remarkable stability of the dominant microbial composition and indicates that the ecosystem has reached equilibrium.

1.2.3. Individual variability within and between individuals

The analysis of caecal microbiota by molecular fingerprint \((\text{CE-SSCP})\) did not reveal in the rabbit the existence of a pattern specific to each individual, stable in time or space \((\text{compartments})\) \((\text{Michelland et al., 2010a})\). Indeed, the inter- and intra-individual bacterial and archaeal communities are of similar magnitude \((\text{Michelland et al., 2010a; Michelland et al., 2010b})\). A high variability of the bacterial community composition between individuals has already been shown in chickens \((\text{Wielen et al., 2002})\), however there are few studies that evaluate the intra individual variation \((\text{repetition of the same individual over time or in space})\). In humans, a pattern specific to each individual is found within the

![Figure 3: Graphical representation of a nMDS analysis of 158 bacterial community CE-SSCP profiles from caecal content (black) soft faeces (green) and hard faeces (red) before (empty circles) and after surgery (disks) that was performed to obtain caecal samples (Michelland et al., 2010a)]
various segments of the colon (ascending, descending and transverse) (Zoetendal et al., 2002) or over time in the faeces (Vanhoutte et al., 2004). The lack of pattern or structure of the archaeal and bacterial community specific to the individual host in rabbits may have originated in the genetic similarity between animals from selected lines and the high standardization of rearing conditions and feeding. These parameters would tend to equalize the influence of the host on the composition of the bacterial community. Recently in humans, (Arumugam et al., 2011) the complete sequencing of bacterial DNA present in the faeces of 200 subjects, identified three types of digestive microbiota or enterotypes. Like the ABO blood group systems, these enterotypes are not specific to the ethnicity of subjects (European, American, Japanese), and unrelated to sex, weight, age or health status. They are distinguished by their taxonomic composition and function (enzymatic equipment). The existence of these enterotypes suggests that a prophylactic or therapeutic action should be specifically tailored to the patient's enterotype. Similar studies are currently under way in animals.

In conclusion, the bacterial and archaeal community of the rabbit caecal ecosystem is composed mostly of species not yet described and very specific to that species. In adult rabbits, the bacterial community composition differs throughout the digestive tract, but remains stable over time and varies little between individuals in the same breeding conditions.

2. Roles of the digestive microbiota

2.1. Role in digestion and feed efficiency

One of the most obvious roles of the digestive ecosystem is its ability to hydrolyze and ferment nutrients. In rabbits and monogastric herbivores, digestion of nutrients takes place mainly in the small intestine through the digestive enzymes of the host. These enzymes hydrolyze most components with the exception of components of plant cell walls or fibres (lignins, cellulose, hemicelluloses, pectins etc...) (Fonty and Gouet, 1989), which are hydrolyzed by bacterial enzymes. Because of the low microbial density and fast passage of digesta in the upper part of digestive tract, dietary fibre that enters the caecum is little modified. This fibre, plus the small intestine’s undigested nutrients and endogenous secretions (mucopolysaccharides, cell debris, enzymes) are the main source of carbon for the microbiota. At the end of the ileal segment, fibre is the major constituent (70% dry matter Gidenne, 1992), while nitrogen compounds come next (15% dry matter) (Villamide et al., 2010). The metabolic activities of microbiota depend on the nature of incoming substrates and are organized in a trophic chain. The first step of the trophic chain (Figure 4), corresponds to the hydrolysis of complex polymers by a variety of hydrolases (polysaccharidases, glycosidases, proteases, peptidases) provided by hydrolytic species in smaller compounds (monosaccharides, amino acids etc...).

These soluble compounds are used by hydrolytic and fermentative species as energy sources. Fermentation processes lead to volatile fatty acid production (VFA: acetic acid, propionic acid and butyric acid), ammonia (NH3) derived from proteolysis, intermediary metabolites (lactic acid, succinic acid, formic acid) and gas (CO2, CH4, H2). All these fermentation reactions allow bacteria to obtain energy for their growth and their multiplication and maintenance of their cellular functions. In rabbits, the role of microbiota in the digestion was first studied through its enzymatic activity and fermentation products (VFA, NH3) (for review Gidenne et al., 2008; Carabaño et al., 2010). Pectinase, xylanase, cellulase and urease are the major enzymes of the microbial ecosystem in rabbits (Carabaño et al., 2010). The hierarchy of bacterial fibrolytic activities (pectinase> xylanase> cellulase) is consistent with that of the digestibility of fibre fractions (pectins> hemicelluloses> cellulose) (Gidenne et al., 2008). The fermentation products are important for the rabbit because the VFA and NH3 are absorbed through the walls of the caecum and colon and are a source of energy for the host. VFA production can cover 30% to 50% of maintenance energy requirements of adult rabbits (Gidenne, 1994). The concentration of VFA in the caecum of an adult rabbit is around 75% acetate, 15% and 10% butyrate propionate. However, these proportions change depending on the age of the animal, the level of intake (Bellier et al., 1995) and feed quality, including rapidly fermentable fibre concentration (Gidenne et al., 2004a). Unlike most herbivores, in rabbits, the ratio of propionate:butyrate is less than 1 because of the characteristics of the microbiota (Adjiri et al., 1992). Finally, the caecotrophy behaviour allows the animal to recycle some of the bacterial proteins. Depending on diet, soft faeces ingestion
contributes about 15% of the total nitrogen ingested, but this proportion can reach 70% for a diet very low in nitrogen (Garcia et al., 2004).

The capacity of the microbiota to provide 30 to 50% of maintenance energy requirements for an adult rabbit is significant, as it impacts the overall digestive efficiency. In rabbits, 30 to 50% of the digestible fraction of digestible organic matter is digested in the caeco-colic segment (Gidenne, 1992; Gidenne et al., 2000). In mice, the involvement of the microbiota in feed efficiency has been proved by observing that axenic mice (without microbiota or "germ free") ate more than conventional mice to maintain body weight (Corthier, 2011). Also, when conventional microbiota were introduced into germ-free mice, there was a 60% increase in body fat, concomitant with a decrease in feed intake by 30% in two weeks (Backhed et al., 2004). Moreover, the transfer of the microbiota from obese mice to germ-free mice induced an increase in the energy extraction from ingested diet and a greater weight gain than that induced by the transfer of lean mice microbiota to germ-free mice (Turnbaugh et al., 2006). Thus, it is demonstrated that the microbiota is involved in feed efficiency in mice. In terms of composition, it has been shown in humans and mice that obese subjects had a ratio of Firmicutes / Bacteroides higher than in lean individuals (Ley et al., 2005; Ley et al., 2006) and less diversity (Turnbaugh et al., 2009). To our knowledge no study in rabbits has helped to connect the feed efficiency and characteristics of the composition of the microbiota.

![Trophic chain of food carbohydrate](https://example.com/image.png)

**Figure 4:** Trophic chain of food carbohydrate according to Bernalier-Donadille et al. (2004).

### 2.2. Role in defense against infectious agents and in the intestinal immune system

The intestinal immune system of the rabbit (GALT for Gut Associated Lymphoid Tissue) is mainly located in the small intestine and colon, as in most mammals, but with two additional special structures: the **sacculus rotondus**, whichis located at the ileo-caecal junction and the vermiform appendix, located at the end of the caecum. The GALT contains more immune cells than the whole body (almost 70% in man Corthier, 2011). In the small intestine GALT consists of organized lymphoid aggregates: Peyer's patches and isolated cells scattered in the lamina propria and the epithelium of the villi (for review Fortun-Lamothe and Boullier, 2007). The germ-free mouse model, compared to conventional mice, revealed the fundamental role of the intestinal microbiota on the development and functions of the GALT. Beside their barrier role, microbiota mainly stimulates immune organs and cell development, diversification of antibodies and mechanisms of oral tolerance.

#### 2.2.1. Barrier role

The concept of barrier (or colonization resistance) is based on the fact that the microbiota permanently implanted in the digestive tract hinders the implantation of exogenous pathogenic bacteria (Berg, 1996). Indeed, in germ-free animals, the transport of antigen across the intestinal mucosa is increased.
Different mechanisms have been proposed to explain the barrier effect: i) Commensal bacteria adherence to the mucosa can prevent attachment and entry of pathogenic bacteria. In rabbits, the filamentous bacteria that colonize the ileum reduce the attachment of enteropathogenic *Escherichia coli* (Heczko et al., 2000). ii) the microorganisms compete for nutrients to maintain their ecological niche and habitat by consuming all resources. iii) the bacteria are able to inhibit the growth of competing bacteria by producing antimicrobial substances (Guarner and Malagelada, 2003).

2.2.2. Role of microbiota in the maturation of intestinal mucosa and angiogenesis

The role of the microbiota on the development of the intestinal mucosa was demonstrated by comparing the intestinal epithelium of germ-free animals to conventional animals. The caecum of germ-free rabbits is enlarged by 6 - 10 times compared to that of conventional rabbits (Fonty et al., 1979; Coudert et al., 1988). In germ-free mice the turnover rate and the number of crypt cells was reduced compared to conventional animals, suggesting that the microbiota reduced cell proliferation in the colon (Guarner and Malagelada, 2003). In germ-free mice, GALT is poorly developed and is comparable to that of a newborn, with a low density of lymphoid cells in the intestinal mucosa, reduced Peyer's patch and low blood immunoglobulin concentration. Some Gram-negative bacteria species, such as *E. coli* and *Bacteroides*, appear to play an important role in this stimulation since their mere presence in the digestive tract of gnotoxenic mice is able to cause a stimulation equal to half of that measured with a complex intestinal microbiota. Indeed, the polysaccharide wall of these bacteria plays an important role in activating the immune system (Mazmanian et al., 2005). Furthermore, network of blood vessels of the intestinal villi of germ-free mice is only half as dense as in germ-free mice inoculated with conventional microbiota. In germ-free mice growth of the networks of blood vessel development was stopped prematurely (Stappenbeck et al., 2002).

**Figure 6:** Schematic representation of antibody repertoire development in rabbit from Fortun-Lamothe and Boullier (2007).

2.2.3. Role in the diversification of the primary repertoire of antibodies

In rabbits, the diversification of the primary repertoire of antibodies continues after birth and is dependent on bacterial stimulation. This diversification begins before birth and ends at the age of 10-12 weeks (Figure 6). Up to 2-3 weeks of age the young rabbits have their narrow neonatal repertoire of antibodies. The establishment of the primary repertoire of antibodies takes place between 4 and 8 weeks of age by recombination processes of nucleotides, gene conversion and somatic hypermutation in the GALT and particularly in the vermiform appendix (Mage et al., 2006; Hanson and Lanning, 2008). The microbiota are essential to the production and diversification of the first antibody repertoire (Lanning et al., 2000) necessary for the animal to fight effectively against various pathogens.
Inoculation of several intestinal bacteria in sterile rabbit vermiform appendix, showed that *Bacillus subtilis* and *B. fragilis* together stimulate B cell proliferation and diversification of genes encoding the immunoglobulin (Rhee *et al*., 2004). More recently, Severson *et al*. (2010) showed that the spores of *Bacillus* stimulated the GALT by a recognition mechanism of superantigen present at the surfaces of spores.

2.2.4. Role in the development of oral tolerance

Although the GALT is continually in the presence of a considerable amount of antigens such as food proteins and commensal microorganisms, it does not develop an immune response, suggesting a host tolerance towards these antigens. The establishment of tolerance mechanisms is also dependent on the presence of the microbiota and takes place early in the life of the host (Fortun-Lamothe and Boullier, 2007).

In human medicine, the hygiene hypothesis is that the lack of stimulation or exposure to pathogens and symbiotic microorganisms (microbiota) or frequent use of antibiotics in young children increases the susceptibility of patients to develop allergic disorders and autoimmune diseases. This phenomenon is linked to impaired development of the immune system in relation to changes in the composition of the microbiota (Okada *et al*., 2010). This hypothesis was supported by recent observations in pigs raised in three different health conditions (outdoor vs. building vs. in an isolator with antibiotic treatment). Thus, animals reared in isolators have an altered microbiota composition and a higher expression of genes involved in inflammatory immune response (Mulder *et al*., 2009).

3. Plasticity of microbiota

Variability in the structure and the functions of microbiota suggests that they could contribute to normal digestive status of rabbits but also to their digestive disorders. Given the physiological roles attributed to microbiota, influencing their composition seems a promising way of improving rabbit breeding in terms of health preservation and feed efficiency. However, it remains to define what would be an appropriate time scale.

3.1. Microbiota implantation and ecological succession of species

Traditionally, the mammal gastrointestinal tracts have been considered sterile *in utero*, however recent studies demonstrated that meconium from healthy newborn were not completely sterile and that a prenatal mother-to-child efflux of commensal bacteria may exist (Jimenez *et al*., 2008) but both number and diversity are low (Koenig *et al*., 2011). Microbial colonization really begins at birth in contact with the mother and the immediate environment (birth canal, close to the nest and feed) (Berg, 1996). Like all mammals, the introduction of species is orchestrated by an ecological succession of species. In rabbits, this succession was first studied by culture techniques (Gouet and Fonty, 1973, 1979; Kovacs *et al*., 2006) and recently molecular tools (Combes *et al*., 2011). At two days old, the bacterial density is already high in the caecum (10⁹ 16S RNA copies / g) and increases to reach its maximum at 21 days of age (10¹¹ - 10¹² copies of rDNA 16S.g-1). At this point, the rabbit is still suckling, but has already begun to eat solid food (Gidenne *et al*., 2010c). During the first weeks of life, the caecal bacterial community is composed of equal numbers of strict anaerobes and facultative anaerobes; then the abundance of the latter falls rapidly and may disappear in some individuals after weaning (Gouet and Fonty, 1979). Bacteria of the *Bacteroides Prevotella* group were detected from 2 to 3 days of age (Kovacs *et al*., 2006; Combes *et al*., 2011) to reach a peak at 21 days (10¹⁰-10¹¹ copies of rDNA 16S.g-1 Combes *et al*., 2011). Moreover, seven days after birth, archaea are present in the caecum at a significant level (10⁵ copies of 16S rDNA / g) (Combes *et al*., 2011). The implantation of archaea seems to occur later than that of bacteria since it reaches its maximum density at 35 days of age (Figure 1).

Molecular fingerprints of the bacterial community allowed, for the first time in rabbits and more completely than in other species, the dynamics of the establishment of the bacterial community present in the caecum to be described (Combes *et al*., 2011). The caecal bacterial community is gradually changing, with a shift in terms of composition and relative abundance (Figure 6). A gradual
establishment of an increasingly diverse community is observed, that seems to reach a climax at 70 days of age (Combes et al., 2011).

3.2. Defining time windows of permissiveness

In mammals, the colonization of the gut begins at birth. Indeed, at this time of life, there is probably little or no barrier to the installation and development of microorganisms. According to Curtis and Sloan (2004), the digestive community of a newborn mammal is a subset of a wider meta-community including all species capable of living in the digestive tract. For example, communities whose environment is similar, have different compositions because they are formed by random sampling from the meta-community around them (mother, bedding, cage, air, etc.). Indeed, the composition of caecal microbiota of young rabbits is highly variable between individuals up to 49 days of age (Figure 6) (Combes et al., 2011). Conversely, at 70 days of age the caecal microbiota composition is very homogeneous between individuals (Figure 6). This observation supports the lack of individual specificity of the microbiota (see above). But it also allows us to define an action window (0-49 days) during which it would be possible to modify the microbiota. This action window corresponds to a period of permissiveness in which the barrier effect of the microbiota or host immunity allows the installation of new species, beneficial or pathogenic to the host.

![Figure 6: Age-related variability of the composition of the bacterial communities in the rabbit caecum. Each point represents an individual's microbiota: the closer the points are together, the more similar are the microbiota (Combes et al., 2011).](image)

Three scenarii to engineer the microbiota can be proposed from this analysis of the microbiota implantation dynamics: 1 - Modify the initial composition: the element of chance in the initial composition of the microbiota can be considered as a possible period for manipulation of the original composition; this manipulation period would take place in the nest. 2 – Modify the ecological succession of species: the high variability within age groups persisted up to 49 days, which in rabbits is a period of high digestive health risk. Since the rabbit consumes solid food from 17 days of age (Padilha et al., 1995; Fortun-Lamothe and Gidenne, 2000), the path of a nutritional modulation of the microbiota could be relevant. 3 – Maturation acceleration: We have shown that whatever the initial microbiota composition, the phenomenon of ecological succession seems to lead to a bacterial community which is very similar between individuals (Combes et al., 2011). Therefore, a course of action might be to speed up the installation process so as to accelerate progress towards a climax community. This could correspond to a stable community, as in adult rabbits which are less subject to digestive troubles.

4. Potential ways to engineer the rabbit digestive ecosystem

Two methods can be considered: those that act on the intrinsic factors and those acting on extrinsic factors to the ecosystem (Mackie et al., 1999). The extrinsic factors concern the immediate
environment’s microbial community, the maternal microbiota composition (genital tract, intestinal tract, and skin) and nutritional factors that act throughout the development of the animal. The intrinsic factors are those related to the host. They are likely to influence the ecological succession or the population balance. They correspond to the influence of host genetics, physiological state, qualitative and quantitative availability of endogenous nutrients, pH and redox conditions, temperature, motility of the intestinal tract which determines the rate of passage of digesta, bile salts and other endogenous secretions, immune response and finally the presence of receptors in the host responsible for host-microbiota interactions (dialogue).

4.1. Influence of the immediate environment on colonization

The immediate environment at birth plays a role in the initial colonization of the digestive tract. One extreme illustration of this is observed in animals submitted to germ-free breeding. Indeed, if the birth occurs in a totally sterile environment, there will be no microbial colonisation, and a rabbit without microbiota cannot survive for long. Moreover, the composition of the microbiota of rabbits raised in a pathogen-free system (SPF) differs from those raised in conventional farming: fibrolytic population density is greater in SPF rabbits (Bennegadi et al., 2003).

The meta-community of the immediate environment that serves as a reservoir for colonization of the digestive tract of young rabbits came from the birth canal of the rabbit, gastrointestinal tract, and fur (direct contact and hairs deposited in the nest). Moreover, during nursing, the doe leaves some faecal pellets in the nest that are eaten by the pups (Moncomble et al., 2004; Kovacs et al., 2006). This behaviour may contribute to the early implantation of the microbiota in neonates. The prevention of ingestion of maternal faeces by the pups delayed the implantation of Bacteroides compared to pups which had access to mother’s faeces in the nest. However, this difference did not persist after eight days of age (Kovacs et al., 2006). The influence of the caecal microbiota of the nursing mother rather than the biological mother on the pup’s caecal microbiota’s initial composition was demonstrated by Abecia et al. (2007c). DDGE analyses showed that at 26 days of age composition of microbiota of fostered pups was closer to the cohabiting pups than to that of their own non-fostered brother.

Finally, the breeding environment (nest box hygiene, atmosphere) and the breeder (handling of pups for fostering for example) are also sources for microbial colonization of the digestive tract. In pigs separated from their mothers and receiving a milk substitute, the structure of microbiota is more dependent on the environment in which they are raised than their genetic origin (Thompson and Holmes, 2009). In pigs, the composition of faecal microbiota and ileal mucosa microbiota is influenced by the type of farming (outdoor vs. building vs. in an isolator with antibiotic treatment). Under these conditions, these differences in microbiota composition persisted until the end of the experiment (56 days old) (Mulder et al., 2009). In humans, it was shown that birth route (cesarean or vaginal), type of milk (breast milk vs infant formula) or antibiotic use influence the initial composition of the microbiota (Penders et al., 2006). However, the effect of this initial microbiota composition on the final composition of the microbiota in adults has not been demonstrated.

4.2. Influence of nutrition

The food is a key factor affecting the balance of microbial populations in the digestive tract. It conditions the supply of nutrients and energy to the ecosystem. During the biodegradation of the food, it acts on the physicochemical parameters of the medium such as pH, redox potential, metabolite concentrations, and the size and density of particles. In turn, these parameters determine the balance of microbial communities (Fonty and Chaucheyras-Durand, 2007). Although the effect of diet on the microbiota including fibre intake has been the subject of numerous studies (for review Gidenne et al., 2008), it remains unclear due to limitations of traditional techniques of microbiology. In most studies only the major taxonomic groups (Bennegadi et al., 2003) or functional groups (Boulahrouf et al., 1991) were considered.

4.2.1. Effect of weaning

Suckling rabbits using a cow’s milk substitute induced significant qualitative and quantitative changes in caecal microbiota between 0 and 11 days of life (Fonty et al., 1979). However, in this experiment none of the rabbits fed cow’s milk survived beyond 14 days. In rabbits, weaning ie the transition to solid food is
progressive. From 17-18 days of age, consumption of solid food takes place gradually while the proportion of milk ingested decreases (Gidenne and Lebas, 2006). When rabbits were subjected to an exclusively milk diet (without access to solid food) until weaning, development of the caecum and pectinolytic and xylanolytic activity were lower and the biodiversity index was lower at 30 days than in controls. Nevertheless, differences fade at 37 days (Combes et al., 2008). Furthermore, ingestion of milk appears to delay colonization by celluloytic bacteria without affecting the population of E. coli (Padilha et al., 1996; Padilha et al., 1999). Weaning seems to have a beneficial effect on the maturation of the caecum and colon. Early weaning increases the weight of the organs and their contents without any effect on mucosal morphology (Gallois et al., 2005) or strictly anaerobic bacteria (Kovács et al., 2012), stimulates fermentation activity (Kovács et al., 2012) and accelerates the maturation of GALT (for review Carabaño et al., 2010).

4.2.2. Effect of the feed intake level
Dietary restriction is one of the most effective non-drug ways to protect the rabbit against non-specific enteropathy (Gidenne, 2003; Gidenne et al., 2012). However the mechanisms of action remain to be elucidated (Martignon et al., 2010a). The morphology of the intestinal mucosa, the maltasic and fibrolytic activity, concentration of VFA and finally the structure and diversity of caecal microbiota were not affected by a reduction of 25% in the food intake after weaning (Gidenne and Feugier, 2009; Martignon et al., 2010a). Conversely, Abecia et al. (2007b) showed that the structure of the caecal microbiota was influenced by the level of intake of does nursing 5 or 9 rabbits.

4.2.3. Effect of the quantity and quality of the fibres
Feeding rabbits with a fibre-deficient diet results in a higher frequency of enteropathy (Gidenne et al., 2004a; Gidenne et al., 2010b). A reduction in indigestible fibre leads to: i) Alterations in the fermentation profile (decrease of VFA, a sharp increase in propionate and increase and decrease of acetate and butyrate), ii) A change in enzyme activity (decreased fibrolytic activity), and iii) A change in the composition of the microbiota: the structure of the caecal bacterial community (composition and relative abundance of species) is altered (Michelland et al., 2011) but not its diversity (Rodriguez-Romero et al., 2009; Michelland et al., 2011). The quantities of the major bacterial divisions studied decrease (Bennegadi et al., 2003; Michelland et al., 2011). All these microbial and environmental changes are observable on the second day after the change of diet and remained stable throughout this new dietary period (Michelland et al., 2011). These results also showed that the bacterial community of the rabbit caecum is able to change and adapt rapidly to reach a new equilibrium in response to a nutritional disturbance (e.g. fibre deficiency).

Fibre quality is one of the most prevailing factors. Several studies have shown that an intake of rapidly fermentable fibre (pectins and hemicelluloses) stimulates fibrolytic activity and the VFA concentration in the caecum (Gidenne et al., 2010a). The most rapidly fermentable fibres such as pectins are probably the most decisive for the caecal microbial activity, as shown by Garcia et al. (2002). Moreover, several studies have shown the favourable effect of digestible fibre on the digestive health of the rabbit (Perez et al., 2000; Gidenne et al., 2004b). The inclusion of fibres called "soluble" (criterion NDSF), e.g. from beet pulp, also reduces mortality and improves the intestinal mucosa. However, the influence of the level of NDSF on the structure of caecal microbiota remains uncertain (Gomez-Conde et al., 2007; Gómez-Conde et al., 2009) since the animals were given antibiotics in their drinking water (apramycin sulfate and tylosin tartrate).

4.2.4. Effect of the level of protein intake
The protein concentration of the food and its amino acid content have an effect on rabbit digestive health (for review Carabaño et al., 2009; Gidenne et al., 2010b). Thus reducing the protein content (21% vs. 18%; Chamorro et al., 2007) or arginine supplementation (Chamorro et al., 2010) reduced mortality and affected the fingerprint of the ileal and/or caecal bacterial community (RFLP). Arginine supplementation reduced the frequency of detection of Clostridium spp and Helicobacter spp RFLP compatibility profiles (Chamorro et al., 2010). Similarly, lowering the dietary crude protein content led to a reduction in the frequency of detection of Clostridium spp RFLP compatibility profiles (Chamorro et al., 2007)
4.2.5. Influence of the bioavailability of nutrients and food associations
The bioavailability of some nutrients depends on the form in which they are given, on the technological treatment used and also on the other components of the diet with which they are associated in the diet. In broiler sequential feeding, animals are fed in two alternating cycles within 24 to 48 hours. The sum of the two diets provides a balanced diet similar to that of a complete feed used in standard diet. This kind of feeding improved the composition of the microbiota (more lactobacilli and fewer coliforms) (Gabriel et al., 2006). To our knowledge no work on sequential feeding in rabbits is available but this approach could be considered as part of an alternative production system.

4.2.6. Effects of prebiotics
A prebiotic is defined as a "non-digestible food ingredient that positively affects the host by selectively stimulating the growth and/or activity of one or a limited number of intestinal bacteria" (Gibson and Roberfroid, 1995). Prebiotics are mostly short chain carbohydrates (or oligosaccharides) that are not hydrolyzed in the small intestine, and thus arrive unchanged in the caecum and colon. Prebiotics are thus a rapidly fermentable substrate and lead to the production of lactic acid and VFA. Three modes of action are attributed to prebiotics: i) stimulation of the growth of beneficial bacteria for the host, ii) competition by masking the binding sites of pathogenic bacteria to the mucosa and iii) binding to pathogenic bacteria. The two most studied prebiotics are fructo-oligosaccharides (FOS) and manno-oligosaccharides (MOS). FOS stimulates the growth of *Bifidobacteria* and *Lactobacilli*, both of which are considered beneficial bacteria to the host (Gibson and Roberfroid, 1995; Kim et al., 2011). The MOS used in chicken, veal and pork would reduce the risk of digestive tract colonization by pathogenic microorganisms by a mechanism of competitive exclusion. Indeed, mannose binds to type 1 fimbriae, which corresponds to a filament that many bacteria use to bind to host cells. Thus, in chickens supplemented with MOS, salmonellae bind to mannose, thus reducing the carriage density (Oyofo et al., 1989). Depending on the dose used, supplementation with FOS and MOS decreased the density of *Clostridium perfringens* and *E. coli* in chickens (Kim et al., 2011). Moreover, MOS supplementation would alter the structure of the bacterial community of chickens (Corrigan et al., 2011).

In rabbit, studies on the influence of prebiotics concerned mainly growth performance and caecal fermentation activity but the results are contradictory even for the same type of prebiotic (for review Falcao-e-Cunha et al., 2007). According to Falcao-e-Cunha (2007), this lack of consensus may be attributed to variation in experimental factors between studies, but also because of the nature of rabbit feed, which is rich in fibre and thus may contain significant amounts of oligosaccharides. Recently, an effect of MOS on the structure of the mucosa was observed with an increase in the size of ileal villi (Mourao et al., 2006), while inulin did not appear to affect the counts of anaerobic bacteria and *E. coli* (Bónai et al., 2010).

4.2.7. Effects of probiotics
Probiotics are living microorganisms used as feed additives for animals and humans that can modulate the activities of the digestive microbiota in order to improve the health or performance of the host. They
consist of one or more species of live microorganisms, with or without culture residues (Table 3). To act on the digestive caecal ecosystem, the probiotic must arrive alive at its site of action and thus survive the acid attack of the rabbit stomach (pH <2). Yeast (Kimsé et al., 2012), and most of the lactic acid bacteria and spores of the genus *Bacillus* are able to resist to stomach acid (Table 3). Because of the barrier effect exerted by the microbiota, but also of the ecological conditions which are not optimal for its maintenance and growth, a probiotic microorganism cannot develop in a sustainable manner in the gastrointestinal tract. To maintain the probiotic at a sufficient level, it must be evenly distributed.

The biological effects of probiotics are generally highly dependent on the microorganism strains used, on their ability to maintain metabolic activity in the digestive environment and on their cellular concentration (Fonty and Gouet, 1989). In rabbits, according to the literature reviewed by Falcao-E-Cunha (2007), the addition of a probiotic tends to improve growth performance when the breeding conditions are not optimal. Accordingly, recent results confirmed the favourable effect of live yeast on rabbit health (Kimsé et al., 2012). Concerning the action of probiotics on microbiota, Amber et al., (2004) showed that the addition of *Lactobacillus acidophilus* increased the number of cellulolytic bacteria and reduced ureolytic bacteria. Furthermore, the addition of yeast (*Saccharomyces cerevisiae*) increased the proportion of *Ruminococcus albus* (Gidenne et al., 2006), but did not alter the structure or the diversity of the bacterial community (Kimsé et al., 2012).

Some probiotics (lactic acid bacteria) have the ability to adhere to epithelial cells of the host, thus slowing a possible colonization by pathogenic bacteria. Probiotics are also able to produce antimicrobial factors (bacteriocin), or metabolites (lactic acid) or enzymes creating ecological conditions more favourable to the indigenous population. *In vitro*, it was shown that probiotics modulated the host immunity. Finally, probiotics have a direct action on the environmental conditions favourable to the activity of the microbiota (change of pH, redox etc.). In rabbits, the addition of yeast led to an increase of redox without altering the pH (Kimsé et al., 2012).

### 4.2.8. Effect of antibiotics

Since the ban on the use of antibiotics as growth promoter (in 2006), these are currently used therapeutically and can be used on veterinary prescription only. Two major risks exist additionally to the presence of residues in animal products. The first risk is that the presence of antibiotics in the gut of the animal might select resistant bacteria, which can then be transferred to other animals of the same species, other animal species and humans. This transmission can be direct, in the case of contact with the animal, or indirect if the bacteria are released into the environment. This has been particularly highlighted by the emergence of *E. coli* strains resistant to apramycin in humans, although this antibiotic is not used in human medicine (Barton, 2000). The second risk is that an antibiotic use before 8 weeks in rabbits would alter the digestive microbiota, and thus the diversification of the antibody repertoire (secreted by B cells or T cell receptors) (see Figure 5). This has led researchers in human medicine to formulate the "hygiene hypothesis". Therefore, it seems important to avoid all practices which might limit the development of the microbiota such as exposure to antibiotics directly or indirectly, such as treatment of mothers. In rabbits, the effect of antibiotics on the microbiota depends on the molecule used Abecia (2007a). The administration of bacitracin (100 ppm), but not that of tiamulin (100 ppm), reduced fermentation activity of the lactating female (Abecia et al.,
Conversely, the molecular fingerprints (DGGE) performed on the caecal contents showed that tiamulin, but not bacitracin, modified the structure of the bacterial community. In rabbits after weaning, the administration of 100 ppm and 120 ppm apramycin tylosin reduced mortality but also reduced the microbiota diversity (Chamorro et al., 2007). Conversely, a medicated feed containing 500 mg / kg oxytetracycline and 50 mg / kg tiamulin did not change the cellulase and pectinasic activity, caecal counts of anaerobic bacteria or *E. coli* (Bónai et al., 2010).

4.3 Influence of host genetics on microbiota

To study the influence of host genetics is equivalent to answering the following question: is there a genetic effect on implantation and / or the final composition of the microbiota of the host? In humans, the microbiota of individuals within the members of one family is closer than between individuals from different families (Zoetendal et al., 2001). This similarity may result from a genetic effect but the effect of a common environment cannot be ruled out. Indeed, the study of Abecia et al. (2007c), tended to show that the influence of genetic origin played little part in the colonization of the caecal microbiota of young rabbit, since the community structure of fostered pups is closer to that of their cohabiting pups than to that of their non-fostered biological brother. Similarly, in pigs separated from their mothers at birth and nursed artificially, bacterial communities from individuals bred in the same pen were more similar between themselves than to their brothers raised in a different pen (Thompson et al., 2008). In contrast, the composition of the microbiota of obese mice (ob/ob) differs from those of the thin line (ob/+ ) or wild strain (+/+) with an increase in the ratio Firmicutes / Bacteroides (Ley et al., 2005). The microbiota of monozygotic twins are more similar than are the microbiota of identical dizygotic twins (Steward et al., 2005). Finally, greater similarity between the microbiota of mouse pups born to mothers’ sisters is observed compared to the microbiota of mouse pups born to unrelated mothers (Hufeldt et al., 2010). All these three last observations suggest that if the transfer of microbiota from one generation to another is through contact between parents and offspring, the host genetic plays a role.

**CONCLUSION**

Recent technological advances in molecular microbiology have provided new knowledge on the composition of the microbiota in humans and animals. However, in rabbits knowledge of these organisms is still patchy. In humans, the study of the metagenome (all bacterial genes present in the digestive microbiota) has identified three groups of individuals or enterotypes which offer interesting advances for prophylactic or therapeutic actions.

The metagenome analysis tool in the rabbit could provide valuable information about the relationship between the functions of the microbiota and digestive problems. In this context one can also imagine the development of a new probiotic in which the key functions necessary to maintain homeostasis would be integrated. Studies so far indicate a relative plasticity of the digestive ecosystem in rabbits. From them, three hypotheses of modification of the ecosystem were presented in this review i) a control of implantation in the nest, ii) the possibility of controlling the microbiota in the period around weaning and / or iii) an acceleration of microbiota maturation.

All these hypothesis open promising research avenues that may lead to changes in farming practices (weaning age, early access to food), nutrition (quantity and quality of fibre, prebiotic and probiotic) and genetics. Moreover, it may be important to avoid all practices which might limit the development of the microbiota, such as exposure to antibiotics directly or indirectly, e.g. by treatment of mothers, to ensure optimal development of the immune system of young rabbits. However although the final objective, which is to optimize ecosystem services to the host in terms of health and feed efficiency is determined, it must be recognized that the composition in term of species and/or functional gene of the targeted microbiota is not yet known.
